Abstract

This study estimated the effects of welfare reform in the 1990s, which permanently restructured and contracted the cash assistance system in the U.S., on food insecurity—a fundamental form of hardship—of the next generation of young adults. An implicit goal underlying welfare reform was the disruption of an assumed intergenerational transmission of disadvantage; however, little is known about the effects of welfare reform on the well-being of the next generation. Using intergenerational data from the Panel Study of Income Dynamics and a variation on a difference in differences framework, this study exploits 3 key sources of variation in childhood exposure to welfare reform: (1) Risk of exposure across birth cohorts. (2) Variation of exposure within cohorts because different states implemented welfare reform in different years. (3) Variation between individuals with the same exposure who were more likely and less likely to rely on welfare. We found that longer exposure to welfare reform led to decreases in food insecurity of the next generation of households, by about 10% for a 5-year increase in exposure, with stronger effects for women, individuals exposed at least 13 years, individuals exposed at relatively young ages (0-5 years), and individuals whose mothers were not high school dropouts. We found no evidence that Supplemental Nutritional Assistance Program benefits explained any of the observed effects.

Executive Summary

This study estimates the effects of welfare reform in the U.S on food insecurity of the next generation of households and explores potential moderating effects of the SNAP Program. Welfare reform, which took place in the 1990s and is still in effect to this day, led to dramatic caseload declines and increases in employment of low-skilled women. However, large proportions of unmarried mothers, even those who were employed, had trouble making ends meet and experienced extreme material hardships (hunger, eviction, utility shut-offs, and homelessness) in the aftermath of the reforms, suggesting that welfare did not make all families better off and may even have caused some households to become food insecure.

Extremely little is known about whether and to what extent welfare reform had causal effects on food insecurity. A major reason for the lack of information is that the datasets that could potentially be used to answer this question only have information on food security in the midst of or after welfare reform implementation. As such, there is little variation in the timing of welfare reform implementation that could help identify causal effects. However, it is possible to investigate the effects for households of young adults (ages ~19–39 years) who were exposed to welfare reform as children (these households could include their own young children), by exploiting variations in age and duration of exposure to welfare reform. This line of research is important not only for understanding forces shaping food insecurity, but also for testing the implicit assumption underlying welfare reform that the stricter new regime would disrupt the intergenerational persistence of poverty. Recent research suggests that SNAP benefits have been an important source of support in the post-welfare reform era. Indeed, while welfare caseloads have declined dramatically since welfare reform was implemented, SNAP caseloads increased sharply after initially declining in the immediate aftermath of welfare reform. These findings and trends suggest that SNAP may have interacted with welfare reform to affect food insecurity.

Using the waves of the household Panel Study of Income Dynamics that include food security data (1999, 2001, 2003, 2015, 2017), we employ a quasi-experimental research design that exploits variation in childhood exposure to welfare reform and compares target and comparison groups to estimate

effects of childhood exposure to welfare reform on household food insecurity as an adult. More specifically, we exploit two key sources of variation in childhood exposure to welfare reform: First, number of years of exposure varied across birth cohorts and across states of residence in childhood. Second, among those with the same exposure, some households would have been more likely to rely on welfare (target group) compared to other households with similar characteristics but much less likely to rely on welfare (comparison group). Household food insecurity of young adults is measured two ways using USDA definitions: (1) marginal, low, or very low food security, and (2) low or very low food security.

Our findings thus far suggest that:

- Longer exposure to welfare reform led to *decreases* in food insecurity of the next generation of households; a 5-year increase in the number of years exposed to welfare resulted in about a 10% decrease in food insecurity of the next generation for each of the two measures of food insecurity. These results were robust to alternative model specifications and age cohorts studied (in our primary analyses, we included individuals born between 1975 and 1980; in supplementary analyses, we included individuals born between 1980 and 1999).

- The effects were strongest for young adults who were exposed to welfare reform for most of their childhood. More specifically, effects were strongest for individuals who were exposed to welfare reform for 13 or more years during childhood and for those who were age 5 years of age or younger when they were first exposed.

- Welfare-reform induces decreases in food insecurity were larger for women than men, with a statistically significant gender difference for low or very low food security.

- The benefits of welfare reform in terms of reducing food insecurity of the next generation were concentrated among young adults whose mothers had relatively higher levels of education (i.e., young adults whose mothers had completed high school compared to those whose mothers had not completed high school).

- Although Supplemental Nutrition Assistance Program participation varied substantially during the observation period, we found no evidence that the welfare reform-induced declines in food insecurity among young adults reflected increases in SNAP participation.

- Welfare reform-associated declines in food insecurity were larger among young adults who were household heads or partners of household heads than for those who did not live in their own households.

Introduction

Food insecurity, which the U.S. Department of Agriculture (USDA) defines as a lack of consistent access to enough food for an active and healthy life (Coleman-Jensen et al. 2020), is a common form of poverty-related deprivation in the United States and has been associated with a number of adverse health outcomes. Specifically, food insecurity has been associated with diabetes, hypertension, hyperlipidemia, depression, hospitalizations, and all-cause mortality among adults, as well as with birth defects, anemia, cognitive and behavioral problems, and acute and chronic health problems among children (Gundersen and Ziliak, 2018; Walker et al., 2019; Thomas, Miller and Morrissey, 2019). Female-headed households with children were almost four times more likely than married-couple households with children to be food insecure in 2019, with a rate of over 28% for the former group (Coleman-Jensen et al., 2020). Food insecurity has become even more prevalent since the COVID-19 pandemic, with a projected increase of 17 million people over the 2018 figure in the U.S. overall (Gundersen et al., 2021), and a substantial increase among households with children since 2016-2017 (Ahn and Norwood, 2021). Rates of food insecurity also vary substantially across states, ranging from 6.6% in New Hampshire to 15.7% in Mississippi in 2017–2019 (Coleman-Jensen, 2020) and geographic and temporal variations in household food insecurity have been associated with state policies, including those that do not directly target food insecurity such as the Earned Income Tax Credit, unemployment insurance, and minimum wage (Bartfeld and Men, 2017).

The 1996 Personal Responsibility and Work Opportunity Reconciliation Act (PRWORA) and state-level reforms in the early 1990s that preceded it (collectively referred to as welfare reform) represented a major policy shift in the U.S. that aimed to reduce dependence on cash assistance by imposing work requirements, time limits on assistance, and other conditions. The PRWORA legislation ended entitlement to welfare benefits under Aid to Families with Dependent Children (AFDC) and replaced AFDC with Temporary Assistance for Needy Families (TANF) block grants to states, who were granted considerable latitude in establishing eligibility and program rules subject to national guidelines that mandated work requirements and a 5-year lifetime limit on the receipt of cash assistance. The new

(and currently ongoing) focus on employment and contraction of cash assistance stood in stark contrast to the human capital focus of the AFDC program that was established in 1960s as part of the War on Poverty. The Biden administration incorporated a third approach into the 2021 American Rescue Plan by temporarily expanding the current child tax credit for eligible families, making the credit fully refundable and not tied to earnings from labor, and providing some of the credit through direct monthly payments— all for year 2021 only. All three approaches have had the same overarching goal (economic self-sufficiency) but very different strategies (human capital building in the AFDC period, strong employment incentives implemented in the 1990s, and direct cash transfers), but how best to achieve that goal remains an open question.

Food security is a fundamental aspect of economic self-sufficiency. The War on Poverty, which included the implementation of the former AFDC cash assistance program, had largely positive effects on adults and children (Bailey and Danziger, 2014), but the effects on food insecurity—a vitally important outcome in its own right and an excellent marker of economic self-sufficiency—are not known because food insecurity was not defined, measured, and tracked by the USDA until 1996, and a consistent measure was not available until 1999 (Coleman-Jensen, 2020). The reforms implemented in the 1990s ("welfare reform") have led to large declines in welfare caseloads (e.g., average monthly family welfare caseloads in the U.S. fell from 5.05 million in 1994 to 1.10 million in 2017—a 78% decrease) (ACF, 2018) and increases in employment of low-skilled women (by as much as 27 percent) (Fang and Keane, 2004). However, large proportions of unmarried mothers, even those who were employed, had trouble making ends meet and experienced extreme material hardships (hunger, eviction, utility shut-offs, and homelessness) in the aftermath of welfare reform (Teitler, Reichman and Nepomnyaschy, 2004), suggesting that the reforms did not make all families better off and may even have caused some households to become food insecure.

It is not known whether welfare reform had causal effects on food insecurity, either in the aggregate or for at-risk groups such as mothers with low job skills or poor health who may be ill-equipped to cope with the conditions of the work-first regime. A major reason for the lack of evidence

about how welfare reform may have affected food insecurity is that, because the USDA did not start collecting consistent data on food insecurity until 1998, the datasets that could potentially be used to answer this question only have information on food insecurity in the midst of or after welfare reform implementation. As such, although there was substantial variation across states in the timing of welfare reform implementation, there was little observable variation that could help identify causal effects of welfare reform on food insecurity of households affected by welfare reform. One study used CPS data from 1995–1996 and 1998–1999 to estimate effects of welfare reform on food insecurity using variations in welfare policies specifically relating to eligibility of immigrants and found that eligibility restrictions increased food insecurity among immigrants (Borjas 2004).

Although the methodological barriers to identifying the effects of welfare reform on food insecurity of households exposed to the reforms are substantial, it is now possible to investigate the effects of welfare reform on food insecurity of the households of young adults (ages ~19 to ~40 years) who were exposed to welfare reform as children (these households could include their own young children), by exploiting variation in age and duration of exposure to welfare reform during childhood. This variation is driven by the child's birth cohort and when their childhood state of residence implemented the new reforms. This line of research is important not only for understanding the effects of welfare reform on food insecurity, but also for testing the implicit assumption underlying welfare reform that it would disrupt the intergenerational persistence of poverty.

Very little is known about effects of welfare reform on economic self-sufficiency of the next generation. In this study, we address this gap by estimating the effects of welfare reform on food insecurity—a fundamental indicator of economic hardship and human deprivation—of the next generation of households, overall as well as by gender, at different stages of childhood, and for vulnerable subgroups. We also explore potential mediating effects of the Supplemental Nutritional Assistance Program (SNAP), which supplements the food budgets of needy families so they can purchase healthful foods (USDA, 2021).

Background

As indicated earlier, the 1996 PRWORA legislation, often referred to as welfare reform, ended entitlement to welfare under AFDC and replaced the AFDC program with TANF block grants to states. Reforms actually started taking place in the early 1990s through "welfare waivers" that allowed states to carry out experimental changes to their AFDC programs. Statewide waivers were approved in 43 states and constituted the first phase of welfare reform (See Appendix Table 1 for implementation dates by state). Many policies and features of the waivers were later incorporated into PRWORA, most notably work requirements as a condition of receiving benefits and lifetime limits. PRWORA granted considerable discretion to states in establishing welfare eligibility and program rules, resulting in substantial state policy variation within the broad national regime.

Aside from the effects of welfare reform on welfare caseloads and women's employment highlighted earlier, quasi-experimental studies found that the reforms (AFDC waivers or PRWORA) led to declines in women's substance abuse (Corman et al., 2013; Kaestner and Tarlov, 2006) and crime (Corman, Dave and Reichman, 2014) and increases in women's civic participation in the form of voting (Corman, Dave and Reichman, 2017). Effects on marriage, cohabitation, and non-marital fertility of adult women were mixed or weak (Ziliak, 2016). Overall, the effects of welfare reform on the outcomes of women that have been studied suggest that welfare reform increased self-sufficiency. However, the findings of high rates of material hardship following the implementation of welfare reform (Teitler, Reichman and Nepomnyaschy, 2004) suggest that these overall effects may mask substantial variation by women's ability to succeed in the labor market.

In terms of the next generation, quasi-experimental studies have found that PRWORA led to decreased high school dropout (reviewed in Dave et al., 2012) and teen fertility (reviewed in Lopoo and Raissian, 2012), at least in part due to specific provisions regarding school attendance and living arrangements of minor mothers. The studies of dropout focused on girls, as did those of teen fertility, although the latter outcome does not cleanly reflect gender-specific behavior. Another study recently found that welfare reform led to increases in skipping school, damaging property, and fighting among teenage boys and increases in smoking and drug use among both boys and girls, with larger effects for

boys (Dave et al., 2021); this study built on a very limited and inconclusive literature on effects of welfare reform on adolescents (Gennetian et al., 2002) and underscores the importance of considering gender-specific second-generation effects.

We know of only two studies that investigated the effects of welfare reform on economic outcomes of the next generation when they became adults because, until recently, the next generation has not been old enough to study adult outcomes. However, those individuals are now in their twenties and thirties. Hartley, Lamarche and Ziliak (2017) found that welfare reform attenuated the association in welfare participation between mothers and daughters by >50%, with no association for participation in *any* public assistance (welfare, SNAP, or SSI), indicating the importance of SNAP benefits in the post-WR era. Indeed, while welfare caseloads have declined dramatically since WR was implemented, SNAP caseloads have increased sharply after declining in the immediate aftermath of WR (Ziliak, 2013). Vaughn (2018) found that exposure to welfare reform during ages 0–5 years was associated with better adult outcomes (more education and fewer out-of-wedlock pregnancies), with stronger estimated effects for women than men.

Both the Hartley et al. and Vaughn studies addressed very specific questions: The former focused on adult women whose mothers had ever received welfare (not necessarily during the daughter's childhood) and the latter focused on a very specific stage of early childhood and did not consider individuals who were exposed to welfare reform over the age 5 but never between the ages of 0 and 5 as having been exposed. The findings from the Hartley et al. study suggest that welfare reform did not increase self-sufficiency among women whose mothers had ever received welfare, while those from the Vaughn study indicate some better human capital outcomes among women exposed to welfare reform in early childhood but did not assess whether those improvements translated to self-sufficiency. Another contribution of the Vaughn study is the consideration of differential effects by gender and the focus on a specific age range or stage of development, both of which the developmental psychology literature suggests would be important.

This study contributes to the very small literature on second-generation adult economic outcomes

of welfare reform by investigating second-generation effects of the reforms on food insecurity among individuals at risk for having relied on welfare as a child, overall and by gender, age and duration of exposure, and characteristics of their mothers. Welfare reform could affect second-generation food insecurity through a number of channels, the most obvious of which is income during childhood. The increases in maternal employment associated with welfare reform could have increased household income, which could have led to improvements in (second-generation) children's human capital development (e.g., through increased access to high-quality childcare, education, or healthcare) and ultimately their socioeconomic status and food security as adults. However, mothers with few employment opportunities may not have had increases in household income and instead confronted increased hardship under welfare reform, which could have had adverse effects on the next generation through decreased income or maternal investments. Additionally, in some cases maternal employment could have led to a net increase in constraints (e.g., if childcare and transportation expenses were not offset by increases in income), which could have led to adverse effects on the human capital trajectories and food security status of the second generation.

Data and measures

We use data from the Panel Study of Income Dynamics (PSID), which began in 1968 as a nationally representative sample of about 5,000 families and follows the original respondents as well as their descendants. The study focuses on family and individual demographic and economic factors and outcomes. Because young adults in the second (and third) generations can be linked to their parents, the PSID includes information about young adults' circumstances both during childhood and when they became adults. The PSID is well-suited for our analysis for several reasons: (1) It spans the time period before, during, and post-welfare reform. (2) It includes detailed information on family circumstances when young adults were children, as well as during their adulthood. (3) State identifiers are available, allowing the researcher to merge measures of economic and policy environments. (4) The USDA Household Food Security module is available for 5 survey waves during the post-welfare reform era.

We focus our analyses on adults in the 1975-1999 birth cohorts for two reasons.[1] First, as discussed below, these cohorts include adults who were never exposed to the new welfare policy regime as children, adults who were exposed for part of their childhood, and adults who were exposed to the reforms over their entire childhood. Second, these cohorts are now old enough to be able to observe their food security outcomes as adults.

Characterizing welfare reform

Welfare reform was implemented in two general phases. The first phase consisted of pre-PRWORA waivers. Although not federally mandated, pre-PRWORA waivers were implemented in the majority of states by the time the federal PRWORA was enacted in 1996 (Schoeni and Blank, 2000). The second phase of welfare reform came with the enactment of PRWORA. States were required to submit plans for and—once approved, implement—TANF programs subject to federal guidelines and have been required to submit changes to their programs to the U.S. Department of Health and Human Services. States implemented their approved TANF programs between September 1996 (Massachusetts, Michigan, and Vermont) and January 1998 (California) (USDHHS, 1999).

Appendix Table 1 presents the implementation dates for both AFDC waivers and TANF for all states in the U.S.[2] The waivers were introduced in 29 states over a period of 53 months, and TANF was implemented in all states over a period of 17 months. Combining both waivers and TANF, states implemented any welfare reform over a period of 64 months, spanning from October 1992 (MI and NJ being the earliest states to implement waivers) through January 1998 (CA being the last state to implement TANF). In our analyses, we use a single indicator for any welfare reform (AFDC waiver or TANF) in a given a month/year in the respondent's state of residence in childhood.

Food insecurity

During the survey years 1999, 2001, 2003, 2015, and 2017, the PSID included the USDA

---

[1] We show later that our estimates are not sensitive to further restricting our sample to cohorts who were exposed for at least some stages over their childhood.
[2] Data on timing of state implementation of major AFDC waivers and TANF were obtained from USDHHS (1999).

Household Food Security module, which was developed by the U.S. Department of Agriculture and provides the official measures of food insecurity in the U.S. The module consists of 18 questions about food hardship during the past year and the PSID categorizes the level of food security based on the responses to those questions (Appendix Table 2 includes the module and a description of the scoring). A score of 1 or 2 indicates marginal food security and a score of 3 or more indicates low or very low food security. We consider two measures of food insecurity, a broad measure of marginal, low, or very low food security (any positive numerical score) and a narrower measure of low or very low food security (a score of 3 or more).

Methods

Our main analyses are based on a quasi-experimental research design, a variant on a difference-in-difference-in-differences (DDD) setup, that leverages variation in childhood exposure to welfare reform across cohorts and compares target and comparison groups within differentially exposed cohorts, to estimate the intergenerational effects of childhood exposure to welfare reform on household food insecurity of young adults. Consider the following reduced-form baseline specification that directly links food insecurity in the adult's household adult to their exposure to welfare reform during childhood:

Equation 1

$$FI_{imbst}^{2nd} = \alpha Exposure_{imbs|age\,0-17} + \pi(Exposure_{imbs|age\,0-17}) * (Target_{ms,j<t}) +$$
$$X_{imbst}^{2nd}\beta + M_{ms,j<t}^{1st}\theta + Z_{st}\varphi + \sum_{c=age\,5-17} Z_{sc}\varphi_c + State_{s,j<t} + Year_t + Cohort_b \left[+ \sum_s State_{s,j<t} * b\right] \left[+ \sum_s \sum_{b=5year\,cohorts} State_{s,j<t} * Cohort_b\right] \left[+ \sum_s \sum_b State_{s,j<t} * Cohort_b\right] \left[+ (\sum_s \sum_{b=5year\,cohorts} State_{s,j<t} * Cohort_b) * (Target_{ms,j<t})\right] + \varepsilon_{imbst}$$

The outcome, *FI*, captures household food insecurity measured in year *t*, for the *i*th young adult (2nd-generation), born in year *b* to mother *m* (1st-generation) who resided in state *s*. *Exposure* to welfare reform is defined as the number of years that adult *i* was exposed to the new welfare policy regime as a child (ages 0-17). We control for vectors of characteristics of young adults (*X*) and their mothers (*M*). Additionally, to account for potentially confounding of individuals' adult and childhood exposures, we

include a rich set of time-varying state factors (Z) measured at period t (concurrent with the young adult food insecurity outcomes) and at various points over childhood (specifically, when the young adult was age 5, 11, and 17 years old).[3] Models further include fixed effects for the period (*Year*), childhood state of residence (*State*), and single birth year cohort (*Cohort*). We estimate all models using Ordinary Least Squares (linear probability models) and report standard errors adjusted for arbitrary correlation in the error term (ε) across and within individuals in their current residential state (i.e., clustered at the state level).[4]

Identifying variation in the degree of childhood exposure to welfare reform comes from a combination of the young adult's birth cohort and when their childhood state of residence implemented welfare reform. For example, individuals born before 1980 generally reached adulthood by the time PRWORA was enacted in 1996; thus, this group was largely unexposed to welfare reform as children. Individuals born after 1999 were exposed to the new regime for their whole lives; however, they had not reached adulthood by 2017, so their food insecurity as adults is not observed. Individuals born between 1980 and 1999 were differentially exposed to the new regime during childhood, depending on their birth year and timing implementation of welfare in their state.[5]

The population of interest is young adults whose mothers were *at risk of* relying on public assistance, whether or not their childhood household actually relied on welfare. Traditionally, the welfare caseload has consisted primarily of low-educated unmarried mothers (Bitler and Hoynes, 2010). This at-risk population is the target group of mothers for whom welfare reform would be expected to have the largest effects on employment, income, and other household conditions and potentially the largest effects

---

[3] We control for state policy and economic factors (unemployment rate, poverty rate, personal income per capita, minimum wage, refundable EITC, and EITC generosity, each measured at these three critical developmental junctures over childhood, for parsimony). Our estimates are fully robust to broadening the set of these controls to additional or different ages (e.g., ages 0, 2, 7, 14).

[4] Our estimates are not sensitive to estimation via logit or probit regression.

[5] As an example, an individual born in California in 1985 would have been exposed for about 9 years of childhood, since CA implemented major waivers to its AFDC program at the end of 1992 (Appendix Table 1). In contrast, an individual born in Colorado in 1985 would have been exposed for about 5 years of their childhood while an individual born in Colorado in 1980 would not have been exposed at all, since Colorado was a relatively late adopter of welfare reform (mid-1997).

(if any exist) on their children as they transition into adulthood. While we control for a large set of confounding childhood exposures to economic conditions and other policies, the possibility of omitted variables remains. Specifically, childhood exposure to welfare reform (*Exposure*) may be correlated with unobserved state-specific cohort trends. We address this issue by considering a comparison group – adults with mothers who are similar in many ways to the target group but unlikely to participate in public cash assistance programs and therefore not expected to be affected by welfare reform policies. In Equation 1 above, *Target* represents a dichotomous indicator for young adults whose mothers were in the target group (i.e., had mothers who were unmarried with at most a high school education and thus at risk of relying on welfare) versus young adults whose mothers were in the comparison group (and thus not at risk of relying on welfare). As marriage generally precludes eligibility for cash assistance, we follow the convention in welfare reform literature and consider adults with low-educated mothers who were married as our primary comparison group.[6] In supplementary analyses, we assess sensitivity to an alternate comparison group that is also used in the literature: adults whose mothers were unmarried and had more than a high school education, as well as a third comparison group that combines the two (e.g., includes both unmarried mothers with more than a high school education and low-educated married mothers).[7]

The parameter of interest is π, which captures the net effects of an additional year of exposure to welfare reform during childhood on young adult food insecurity, for those growing up with an unmarried low-educated mother (target group) relative to similar individuals from the same cohort and state who grew up in households that were generally ineligible for welfare and thus would not be impacted by the

---

[6] When classifying young adults into target and comparison groups, we consider their mother's marital status when the young adult was born if that took place after welfare reform was implemented in their mother's state of residence, or her marital status at the time welfare reform was implemented if the young adult was born prior to the implementation of welfare reform in the mother's state of residence. This fixed definition of marital status at baseline levels bypasses compositional selection issues that could arise if the definition of the mother's marital status was time-varying over the childhood exposure period. Specifically, if marital status was affected by welfare reform (although evidence on that is mixed; see Ziliak, 2016), then treatment assignment would be endogenous since welfare reform would affect assignment into target and comparison groups and thus bias the estimated treatment effects.

[7] The factors (marital status, educational attainment) used to define the target and comparison groups are subsumed in the vector of controls for maternal characteristics (vector *M* in Equation 1); as such, a separate indicator differentiating the target and comparison groups is not needed in Equation 1.

new policy regime (comparison group).

We extend the baseline specification in various ways to address methodological challenges inherent in our methodology. First, we assess the sensitivity of our estimates to progressively more inclusive controls for unobserved state-specific birth cohort trends. We include, in turn: parametric controls for state-specific linear cohort trends $[\sum_s State_{s,j<t} * b]$; state-specific 5-year birth cohort fixed effects $[\sum_s \sum_{b=5year\ cohorts} State_{s,j<t} * Cohort_b]$; and state-specific single-year birth cohort fixed effects $[\sum_s \sum_b State_{s,j<t} * Cohort_b]$. Although the last specification would normally not be feasible in analyses that rely solely on policy variation across cohorts, an additional source of identifying variation – that between target and comparison groups–allows us to flexibly account for all measured and unmeasured state-specific heterogeneity across cohorts by saturating the models with fixed effects at the level of the state by single-year birth cohort. We also gauge the sensitivity of our estimates to allowing the state-specific-cohort trends to differ across target and comparison groups, flexibly across five-year cohort sets, by interacting the 5-year birth cohort fixed effects with the target indicator:

$$[(\sum_s \sum_{b=5year\ cohorts} State_{s,j<t} * Cohort_b) * (Target_{ms,j<t})].$$

Second, we relax the imposed linearity in Equation 1 on the marginal effects of childhood exposure to welfare reform by assessing non-linear effects of the duration of exposure as well as heterogeneity based on the child's age of exposure. Third, we evaluate differential treatment effects across adult and maternal characteristics since the average effect identified above may mask important heterogeneity in how welfare reform affected families in different situations. We assess heterogeneous effects across gender, because there is evidence that boys and girls respond differently to changes in household circumstances during childhood (Bertrand and Pan, 2013; Kling, Ludwig and Katz, 2005), including welfare reform (Dave et al., 2021). We also evaluate heterogeneity based on maternal human capital. While the target group consists of low-educated (at most possessing a high school degree) unmarried mothers, the subgroup of mothers who did not complete high school would have been particularly disadvantaged in the labor market and may not have been well-equipped to meet the work

requirements under the new welfare regime. Fourth, we consider the mediating effects of current SNAP participation among the (2nd-generation) young adults' households. Doing so indirectly suggests the extent to which welfare reform-associated changes in food insecurity for the young adult children are potentially driven by shifts in SNAP participation versus other factors such as shifts in the household's economic circumstances. Finally, we implement several additional robustness checks, including a falsification check by estimating pseudo-treatment effects of childhood exposure to welfare reform for a group for which we would not plausibly expect any substantial impact – young adults whose mothers were married and relatively highly educated.

Results

Sample characteristics

Table 1 presents weighted sample characteristics of the young adults in the sample. The full sample (~9,800 observations) consists of individuals born between 1975 and 1999 who were at least 18 years old in each of the years 1999, 2001, 2003, 2015, and 2017 and whose mothers who were at least 18 years old and had non-missing marital status and education just prior to WR implementation in their childhood state of residence.[8] The target group consists of individuals whose mothers were unmarried and had at most a high school education. The primary comparison group consists of individuals whose mothers were married and had at most a high school education.

In adulthood, about 11% of the full sample and 13% of the comparison group experienced low or very low food security, compared to about one quarter of the target group. Less than a quarter of both the full sample and the comparison group experienced marginal, low, or very low food security, compared to 40% of the target group. Similarly, young adults in the target group were more likely to receive food stamps. Thus, the target group was more disadvantaged in adulthood than the comparison group and the comparison group was somewhat more disadvantaged than the full sample. Overall, about 12% of the full

---

[8] For young adults born after welfare reform was implemented in their childhood state of residence, we measure these variables at the time of this of her birth (see footnote 6).

sample of young adults (and about 10% of the target group) were not exposed to welfare reform as children, about 26% were exposed but only during their teens, about 30% were exposed between the ages of 6 and 12, and about 20% were exposed for all or most of their lives. About 70% of the young adult observations took place during the last two survey waves we observed—2015 and 2017. The mean age at which we observed the young adults was 27 years.

Appendix Table 3 presents characteristics of the mothers of the young adults in our sample. Education and marital status were measured the year prior to welfare reform implementation,[9] and maternal age was measured both in 1999[10] and when the young adult was born. By design, all of the mothers in the target group were unmarried, while all of the comparison group mothers were married. Mothers in the target group were more likely to be Black and less likely to have completed high school than mothers in the comparison group and (even more so) than mothers in the full sample, indicating that the target group is particularly disadvantaged and thus at high risk of relying on public assistance.

Main analyses

We present baseline estimates from Equation 1 in Table 2, separately for the broad and narrow measures of food insecurity, in Panels A and B respectively. Across all specifications reported in the top panel, we find consistent evidence that childhood exposure to welfare reform significantly reduced the likelihood of food insecurity (marginal, low, or very low food security) among adults in the target group relative to the comparison group. Specifically, the estimate from the most parsimonious specification (model 1) indicates that an additional year of exposure to welfare reform during childhood lowered the probability of marginal, low, or very low food security by about 0.8 percentage points. Controlling for state policies and economic conditions in the adult's childhood state of residence, measured at various ages during their childhood, does not materially alter this treatment effect (model 2).[11]

---

[9] However, as discussed in footnote 6, education and marital status were measured at the time of the birth for young adults who were born after welfare reform was implemented in their childhood state of residence.

[10] We used one point in time for measuring maternal age, so that this control variable was not associated with the rollout of welfare reform across states.

[11] Estimates are also not sensitive to separately controlling for fixed effects for the adult's current state of residence (see Appendix Table 4).

The treatment effects estimated in models (1) and (2) are identified off of two key sources of variation, differences in ages adults were when their childhood states implemented welfare reform and differences in trends across the target and comparison groups within equally exposed cohorts in a given state. The next set of models progressively adds more inclusive controls for potentially confounding trends, and in the process evaluates the identifying assumptions and assesses robustness to dampening or completely switching off alternate sources of variation. Models (3) and (4) add parametric and non-parametric controls for unobserved state-specific cohort trends and model (6) is fully saturated with a set of state-cohort fixed effects, thereby controlling for all observed and unobserved differential cohort trends across each state.[12] These models rely less on the variation in exposure across cohorts, and more on the variation in trends within similarly exposed cohorts across the target and comparison groups. Alternately, model (5) allows the unobserved state-specific cohort trends, across 5-year cohort groups, to differ between the target and comparison groups. Given that the target group is somewhat more disadvantaged at baseline than the control group (Appendix Table 1), it is important to assess if the treatment effects might just be picking up differential trends across these groups. In controlling for these differential trends in model (5), we are relying less on the comparison group for identification and relatively more on the variation in exposure due to age cohort and when states implemented the reforms.

While more saturated fixed effects and trend controls restrict the identifying variation and somewhat reduce precision (models 5 and 6), it is validating that the estimated treatment effects are not materially altered. With the average adult in the target group exposed to the new welfare regime for approximately seven years (mean exposure = 7.3 years) over their childhood, the coefficient magnitudes across these models imply that this mean level of exposure lowered food insecurity by between 5.8 – 7.0 percentage points (or 14.3 – 17.3 percent relative to the mean for the target group).

Panel B reports estimates for the stricter measure of food insecurity—low or very low food security. Though less precisely estimated (the estimates are not uniformly statistically significant), the

---

[12] In the saturated model the main effect of *Exposure*, shown in Equation 1, would drop out since it is perfectly collinear with the state-cohort fixed effects.

estimated effects are statistically significant in three out of the six specifications and are similar across specifications and consistent with childhood exposure to welfare reform resulting in an improvement in the adult household's circumstances, as proxied by a reduction in low or very low food security. The effect magnitudes, evaluated at the mean level of exposure and relative to the outcome mean for the target group, suggest an improvement on the order of 11.5 to 17.7 percent.

Duration and timing of exposure

Estimates from Table 2, based on Equation 1, linearized the effects of each additional year of childhood exposure to welfare reform. We relax the linearity assumption and explore effects of varying levels of exposure duration in Panel A of Table 3. Reported estimates are relative to adults with zero years of exposure to welfare reform. For the broader measure of food insecurity (reported in models 1 and 2), improvements materialize for adults who were exposed longest, for at least 13 years of their childhood – on average by about 14-15 percentage points.[13] For adults exposed minimally between 1-4 years, or even exposed for longer amounts between 5-12 years, there are no economically or statistically significant declines when considering the broader measure of food insecurity. When we turn to the stricter and narrower measure in models 3 and 4, there is some evidence of a dose-response relationship, with declines in food insecurity increasing with the duration of exposure to welfare reform. While the magnitudes are non-trivial, suggesting those exposed longest experienced an improvement by about 7 percentage points, these estimates do not attain statistical significance at conventional levels.

Models reported in Panel B attempt to parse out differential effects of exposure based on the age of the child when his/her mother was initially exposed to welfare reform. Doing so allows us to investigate the extent to which certain periods of child development are more or less sensitive to changes in household circumstances induced by welfare reform (Cunha & Heckman, 2007; Vaughn 2018). Complicating this endeavor is that age of exposure and duration of exposure over the childhood period are perfectly correlated, making it impossible to fully disentangle the separate effects of age and duration of

---

[13] Among this group that was exposed the longest, the effect magnitude is largely similar to that derived from Table 2, for an additional year of exposure multiplied by 15 (midpoint of exposure between 13-18 years).

exposure. To address this challenge, we estimated regression splines that allowed the marginal effect of each additional year of exposure to differ depending on the age range of the child when he/she was exposed. These estimates suggest that children who were relatively young (ages 0-5 years) when their mothers were exposed to welfare reform experienced the strongest declines in food insecurity as adults; each additional year of exposure resulted in an improvement in the broader measure of food insecurity for this group by between 0.8 and 0.9 percentage points. In contrast, additional years of exposure had no meaningful effects if the children were older than age 5 when their state implemented welfare reform. Similarly, for the stricter measure of food insecurity, we find significant negative effects of exposure only when adults were exposed at very young ages. While the marginal effects of exposure are negative for those exposed during the later stages of childhood, those effects are not statistically significant.

In summary, the evidence from Table 3 underscores two complementary points. First, improvements in adult food insecurity associated with welfare reform appear to materialize for adults in the target group that were exposed the longest to the new welfare rules as children. Second, the effects are also largest for, and largely driven by, those who were exposed at very early ages, underscoring the importance of early life circumstances in determining later adult outcomes.

Heterogeneity

We further explore heterogeneity in the treatment effects across gender (Table 4) and across maternal educational attainment (Table 5). In light of our prior discussion and work that has found some evidence that the intergenerational effects of welfare reform (at least on adolescents; see Dave et al. 2021) are gender-specific, it is plausible to expect that men and women may have responded differently as household circumstances shifted due to maternal exposure to the new welfare rules. Estimates reported in Table 4 consistently show stronger welfare reform-associated improvements in food insecurity for adult women relative to adult men, especially for the more intense form of food insecurity (low/very low food insecurity, reported in models 4-6), for which there were no significant improvements for men (thus, all of the overall improvement was for women). These gender patterns are consistent with previous work (Dave et al. 2021), which found stronger unfavorable effects of welfare reform on delinquent behaviors

among male adolescents relative to female adolescents.

While adults in the target group, by definition, grew up in households with (unmarried) low-educated mothers, it is possible that mothers who were particularly disadvantaged in the labor market due to low levels of human capital may have fared quite differently under the more restrictive welfare rules and that this could spill over into differential effects on their children as they transition into adulthood. Estimates in Table 5 broadly indicate that exposure to welfare reform during childhood had little beneficial effects on food insecurity for adults whose mothers had less than a high school education; the overall improvements in food insecurity that we found appear to accrue to the adult children of mothers who had relatively higher levels of human capital, as proxied by having a high school diploma.

SNAP participation

The results presented thus far consistently point to childhood exposure to welfare reform having beneficial effects on food insecurity in adulthood, with some groups (e.g., those exposed at early ages, those with high school-educated mothers, women) experiencing bigger improvements than others. An interesting question arises as to whether the reduction in food insecurity associated with welfare reform is due to greater SNAP participation versus other causes that may include overall betterment in the 2nd-generation adult household's economic circumstances. SNAP eligibility has expanded over the years as have the benefits of the program (Coleman-Jensen et al., 2020), and it is possible that some of the favorable effects of welfare reform on food security among young adults reflected increased use of SNAP benefits.

In Table 6, we assess the extent to which the welfare-reform associated decline in food insecurity among adults in the target group relative to the comparison group reflects expanded SNAP participation. Models reported in the table alternately exclude and include controls for the household's current and past year SNAP receipt. While the treatment effects decline slightly, we continue to find significant improvements in food security conditional on SNAP receipt, and with overlapping confidence intervals we are not able to reject the null hypothesis of similar effect magnitudes across models that alternately exclude and include household SNAP receipt.

We note that SNAP participation is potentially an endogenous mediator since adult program participation could be impacted by childhood exposure to welfare reform. We therefore also estimate models of SNAP receipt as outcomes, to determine whether SNAP receipt during adulthood was itself impacted by exposure to welfare reform as a child. These models indicate no statistically significant or substantive effects of welfare reform on current or past year SNAP receipt.[14] This is consistent with recent findings by Hartley et al. (2021) that welfare reform attenuated the positive link specifically between a mother's participation in AFDC/TANF and her daughter's welfare participation as an adult, but not broadly with respect to the wider set of public assistance programs.

Robustness checks

We conduct several additional checks to verify that our estimated treatment effects are robust to alternate specifications and samples, and to more generally assess their plausibility. Our sample for the main analyses was limited to adults ages 18 and older. It is possible that some of these adults may still be residing with their mothers or part of extended households headed by other family members, in which case the estimated effects on food insecurity would be more reflective of the circumstances of other household adult heads rather than the sample adult's own circumstances. In Appendix Table 5, we restrict our sample specifically to adults who are household heads. These estimates should be interpreted with care since household formation is potentially endogenous to childhood exposure to welfare reform, which was why we did not restrict the sample this way for our primary analyses. Nevertheless, it is validating that we find very similar effects for the restricted sample, with the effects for the stricter measure of food insecurity becoming more precise and somewhat larger in magnitude than in the corresponding main models.

Our main analyses were based on cohorts born between 1975-1999, which include adults who were never exposed, those who were partially exposed, and those who were exposed to welfare reform over their entire childhoods. Including the earlier never-exposed cohorts can be important for fitting

---

[14] The coefficient for past year food stamp receipt is -0.00425 (p-value = 0.33) and for current food stamp receipt is -0.00043 (p-value = 0.91), based on specifications that control for state by 5-year cohort group fixed effects.

cohort-specific trends. In Appendix Table 6, we assess the robustness of the estimates to relying on variation in exposure only among ever-exposed cohorts – those born between 1980-1999; every (target group) adult in these birth cohorts had some exposure to welfare reform during childhood. Our results and conclusions are not materially changed from excluding the cohorts include never-exposed adults.

We present estimates based on an alternate comparison group (unmarried mothers with more than a high school education), as well as a combination of that comparison and our original comparison group (which was low-educated married mothers) in Appendix Table 7. That is, the third comparison group includes both unmarried mothers with more than a high school education and low-educated married mothers. Our estimates were insensitive to these alternative comparison groups.

Finally, we estimate effects for adults whose mothers were married and higher educated as a placebo check, as it would not be plausible to expect substantive or significant effects of childhood exposure to welfare reform for this group. If there were significant effects, it would point to spurious time-varying cohort trends. It is therefore validating that the treatment effects in these models are statistically insignificant, with magnitudes that are small and close to zero (shown in Table 7).

Discussion & Conclusion

This study estimated the effects of welfare reform in the 1990s, which permanently restructured and contracted the cash assistance system in the U.S., on food insecurity—a fundamental form of hardship—of the next generation of young adults. We found that longer exposure to welfare reform led to decreases in food insecurity of the next generation of households, by about 10% for a 5-year increase in exposure, with the stronger effects for women, individuals exposed at least 13 years, individuals exposed at relatively young ages (0-5 years), and individuals whose mothers were not high school dropouts. Receipt of SNAP benefits did not appear to explain any of the associations.

While, overall, welfare reform led to an improvement in circumstances of the next generation of adults, it is important to place the findings in context. We investigated one key indicator of material hardship (or conversely, well-being), but the findings may not translate to other outcomes such as income and assets. In addition, the findings highlight that the improvements in food security associated with

24

welfare reform were not uniform across the relevant population. Notably, men did not fare as well as women and young adults with very low educated mothers (high school dropouts) did not experience improvements in food security. It is important to take such heterogeneity into account when making policy decisions to continue or modify the cash assistance system in the U.S.

Sample Size	5300	5300	5300	5300	5300	5300

Notes: Each column in Panel A and Panel B presents results from separate regression model. Coefficients from fixed effects OLS estimation are reported, with robust standard errors, allowing for correlation of observations within current state of residence, reported in parentheses. All specifications control for childhood state of residence, sociodemographic characteristics of young adults and their mothers (indicators for ages 18-22, 23-27, 28-32, 33-37, and 38-42, gender, and the mother's race/ethnicity, education and marital status (timing described in text), and age when the young adult was born) and for state policies and economic conditions during year of interview (unemployment rate, personal income per capita, poverty rate, indicators for the SNAP policy index, percent of low-income children who are uninsured, refundable EITC, EITC rate, minimum wage, log of the number of Medicaid beneficiaries, and log population). All specifications further control for fixed effects for the child's state of residence, cohort, and year of interview (when food security outcome was assessed). States policies during childhood include the unemployment rate, poverty rate, personal income per capita, minimum wage, refundable EITC, and generosity of EITC, all measured when the adult was age 5, 11, and 17. In Model 6, the main effect of exposure is captured by the State*Cohort fixed effects. Asterisks denote significance as follows: *** p-value ≤ 0.01; ** 0.01 < p-value ≤ 0.05; * 0.05 < p-value ≤ 0.10.

Appendix Table 2: Core Food Security Module Questions

Questions Used To Assess the Food Security of Households in the CPS Food Security Supplement

1. "We worried whether our food would run out before we got money to buy more." Was that often, sometimes, or never true for you in the last 12 months?
2. "The food that we bought just didn't last and we didn't have money to get more." Was that often, sometimes, or never true for you in the last 12 months?
3. "We couldn't afford to eat balanced meals." Was that often, sometimes, or never true for you in the last 12 months?
4. In the last 12 months, did you or other adults in the household ever cut the size of your meals or skip meals because there wasn't enough money for food? (Yes/No)
5. (If yes to question 4) How often did this happen—almost every month, some months but not every month, or in only 1 or 2 months?
6. In the last 12 months, did you ever eat less than you felt you should because there wasn't enough money for food? (Yes/No)
7. In the last 12 months, were you ever hungry, but didn't eat, because there wasn't enough money for food? (Yes/No)
8. In the last 12 months, did you lose weight because there wasn't enough money for food? (Yes/No)
9. In the last 12 months did you or other adults in your household ever not eat for a whole day because there wasn't enough money for food? (Yes/No)
10. (If yes to question 9) How often did this happen—almost every month, some months but not every month, or in only 1 or 2 months?

(Questions 11-18 were asked only if the household included children age 0-17)

11. "We relied on only a few kinds of low-cost food to feed our children because we were running out of money to buy food." Was that often, sometimes, or never true for you in the last 12 months?
12. "We couldn't feed our children a balanced meal, because we couldn't afford that." Was that often, sometimes, or never true for you in the last 12 months?
13. "The children were not eating enough because we just couldn't afford enough food." Was that often, sometimes, or never true for you in the last 12 months?
14. In the last 12 months, did you ever cut the size of any of the children's meals because there wasn't enough money for food? (Yes/No)
15. In the last 12 months, were the children ever hungry but you just couldn't afford more food? (Yes/No)
16. In the last 12 months, did any of the children ever skip a meal because there wasn't enough money for food? (Yes/No)
17. (If yes to question 16) How often did this happen—almost every month, some months but not every month, or in only 1 or 2 months?
18. In the last 12 months did any of the children ever not eat for a whole day because there wasn't enough money for food? (Yes/No)

Coding of Responses

Questions 1-3 and 11-13 are coded as affirmative (i.e., possibly indicating food insecurity) if the response is "often" or "sometimes." Questions 5, 10, and 17 are coded as affirmative if the response is "almost every month" or "some months but not every month." The remaining questions are coded as affirmative if the response is "yes."

Assessing Food Security Status in Households without Children

Households without children are classified as *food insecure* if they report 3 or more indications of food insecurity in response to the first 10 questions; they are classified as having *very low food security* if they report 6 or more food-insecure conditions out of the first 10 questions.

Assessing Food Security Status in Households with Children Age 0-17

Households with children are classified as *food insecure* if they report 3 or more indications of food insecurity in response to the entire set of 18 questions; they are classified as having *very low food security* if they report 8 or more food-insecure conditions in response to the entire set of 18 questions.

The food security status of children in the household is assessed by responses to the child-referenced questions (questions 11-18). Households reporting two or more of these conditions are classified as having *food insecurity among children*. Households reporting five or more are classified as having *very low food security among children*.

Appendix Table 3
Weighted Maternal Characteristics, PSID

	1 Full Sample	2 Comparison Group	3 Target Group
Maternal Characteristics			
Age in years in 1999, mean (s.d.)	42.17 (7.08)	41.60 (7.26)	39.96 (7.74)
Age in years when young adult was born, mean (s.d.)	26.85 (5.04)	25.50 (5.05)	24.50 (5.48)
Race			
White	.804	.821	.330
Black	.153	.122	.639
Other	.043	.057	.031
Educational attainment year before welfare reform implementation (or at time of birth of child if child was born after welfare reform) Less than high school	.095	.156	.371
High school education	.401	.844	.629
More than high school education	.504	n/a	n/a
Married	.87	1.00	.00
N	9,847	3,925	1,375

Notes: Figures are proportions unless indicated otherwise. Full sample consists of mothers (of young adults who were at least 18 years of age and born in 1975 or later) who were age 18+ years when the young adult was born and had known marital status and education when the young adult was first exposed to welfare reform as a child. Target group consists mothers of young adults in the full sample who had at most a high school education and were unmarried when the young adult was first exposed to welfare reform as a child. Comparison group consists of mothers of young adults in the full sample who had at most a high school education and were married when the young adult was first exposed to welfare reform as a child.
